Robust increases in erythropoietin production by the hypoxic fetus is a response to protect the brain and other vital organs

Kari A. Teramo1, Miira M. Klemetti1 and John A. Widness2

Fetal erythropoietin (EPO), in addition to regulating erythropoiesis, has also tissue-protective properties based on its anti-inflammatory, anti-apoptotic, antioxidant, and neurotrophic effects. Notably, EPO concentrations needed for tissue protection are 100–1000 times higher than concentrations needed for regulating erythropoiesis. This dual effect of EPO is based on EPO-receptor (EPO-R) isoforms, which differ structurally and functionally. We hypothesize in this Integrated Mechanism Review that during severe fetal hypoxia the observed, but poorly understood, marked increases of fetal plasma EPO concentrations occur to protect the brain, heart, and other vital fetal organs. We further hypothesize that the concurrent marked increases of EPO in the amniotic fluid during fetal hypoxia, occur to protect newborn infants from necrotizing enterocolitis. This review presents experimental and clinical evidence in support of these hypotheses and points out unknown or poorly understood functions of EPO in the fetus. If these novel hypotheses are correct, the importance of fetal EPO as an antenatal hypoxia biomarker will become apparent. It will also likely point the way to important diagnostic and therapeutic fetal and neonatal interventions.

BACKGROUND

Erythropoietin (EPO), a glycoprotein hormone with a molecular weight of 30.4 kDa, is primarily responsible for regulating erythrocyte production in adults, newborn infants, and fetuses. During pregnancy, maternal serum EPO levels increase linearly from 16 to 65 mU/ml at term to meet the hematopoietic needs of pregnancy. Prior to 30 weeks of gestation in the fetus, the liver is the main organ of EPO production, after which a gradual transition to renal EPO production occurs. During normal oxygenation at term, fetal EPO production takes place mainly in the kidneys. Because EPO is not stored in tissue and does not cross the placenta, steady-state fetal plasma EPO concentration reflects equal, opposing rates of EPO synthesis, and elimination. During the last trimester of normal pregnancy, normoxemic human fetal plasma EPO hormone concentrations range from 10 to 50 mU/ml prior to labor. Concurrent amniotic fluid EPO concentrations during normal fetal oxygenation range from 2 to 20 mU/ml. Fetal plasma EPO concentrations under both normal and fetal hypoxic conditions average 2.6 times higher than concurrent amniotic fluid EPO levels.

This Integrated Mechanism Review focuses on important non-hematological actions of EPO that are being increasingly recognized in the fetus and the newborn infant. Our central hypothesis is that the observed marked increases of fetal EPO during severe fetal hypoxia occurs in order to protect its brain, heart, and other vital organs from the deleterious effects of severe hypoxia. We further hypothesize that the purpose of the concurrent increase in amniotic fluid EPO concentration during severe fetal hypoxia is to protect the intestine from necrotizing enterocolitis (NEC). In this review, the known effects of EPO on fetal erythropoiesis and its tissue-protective properties are described to support these hypotheses based on existing experimental and clinical evidence. If our hypotheses are correct, they will further emphasize the importance of fetal EPO as an important antenatal hypoxia biomarker, and suggest potential new therapeutic approaches.

Several unknown or poorly understood EPO effects in the fetus include: (1) what is the contribution and the role of the placenta in increasing fetal EPO production during hypoxia; (2) how and through what mechanism is amniotic fluid EPO concentration also increased during fetal hypoxia; (3) how and through what mechanism does fetal EPO reach the intestine; and (4) through what mechanism and in which fetal organs does EPO exert protective effects during tissue hypoxia? As a basis for clarifying these uncertainties, Fig. 1 depicts maternal EPO production during normal pregnancy and the postpartum period. It also depicts fetal EPO production during anemia and chronic hypoxia in the context of previously documented or hypothetical effects of EPO on the fetus and the newborn infant.

Role of EPO in fetal red cell production

Fetal red cell production is regulated by EPO to maintain normal steady-state erythropoiesis and blood hemoglobin levels during normoxic conditions and to accelerate erythropoiesis during tissue hypoxia due to anemia and other causes. EPO synthesis is regulated by the partial pressure of oxygen (pO2) of blood perfusing the oxygen sensitive renal peritubular fibroblasts, where it is mediated by the hypoxia-inducible transcription factor (HIF) complex. EPO in amniotic fluid

Amniotic fluid EPO concentrations correlate highly with fetal plasma EPO concentrations both in normal and abnormal

In pregnancies complicated by type 1 diabetes or hypertension, amniotic fluid EPO concentrations obtained within 2 days before birth and prior to labor are highly correlated with fetal plasma EPO concentrations, \( r = 0.86 \) and \( r = 0.89 \), respectively.\(^5\) In these pregnancies, both normal amniotic fluid EPO levels (i.e., \(<20 \text{ mU/ml}\)) and pathologically elevated amniotic fluid EPO levels (i.e., \( \geq 50 \text{ mU/ml}\)) correlate highly significantly with fetal plasma EPO levels (Fig. 2). In contrast, slightly elevated (i.e., \( 20–50 \text{ mU/ml}\)) do not. The latter may be explained by a delay in the increase in amniotic fluid EPO concentration relative to the rate of increase in fetal plasma EPO concentration during fetal hypoxia.\(^6\)

Serial measurements of amniotic fluid EPO levels in individual pregnancies demonstrate that once the fetus becomes hypoxic, the amniotic fluid EPO concentration starts to increase exponentially.\(^7\) It is noteworthy from serial amniotic fluid EPO measurements in individual cases that once amniotic fluid EPO levels reach pathological levels (i.e., \( \geq 50 \text{ mU/ml}\)), amniotic fluid concentrations increase exponentially.\(^8\) Calculated from these exponential amniotic fluid EPO increases, the daily increase in amniotic fluid EPO levels can be as much as \( 30–40 \text{ mU/ml} \).\(^9\) This is equivalent to daily increases of \( 80–100 \text{ mU/ml} \) in plasma during fetal hypoxia. Once fetal hypoxia triggers increased fetal EPO production, pathological amniotic fluid EPO levels do not level off or decrease; instead, they continue to increase.\(^10\)

In clinical intrauterine red cell transfusion studies of Rh-immunized pregnancies, fetal hemoglobin concentrations ranging from 11 to 159 g/l obtained at the first cordocentesis—and thus prior to fetal red cell transfusion—correlate inversely with concurrent amniotic fluid EPO levels that range from 2 to 42 mU/ml.\(^11\) This correlation and the slopes of this relationship are similar before and after 27 weeks of gestation (\( r = -0.57 \) and \( r = -0.49 \), respectively). This observation is consistent with the
observation that only low circulating EPO concentrations are required for red cell production even when fetal hemoglobin levels are extremely low.18 Despite this, even anemic fetuses markedly increase their EPO production as indicated by exponential increases in amniotic fluid EPO levels when already anemic fetuses become severely hypoxic.17 This suggests a different function for EPO under these circumstances.

It is unknown how EPO reaches amniotic fluid in human pregnancy. In the ovine pregnancy EPO mRNA and EPO hormone are both present in the fetal amnion and chorion membranes during the last trimester of pregnancy.19 This indicates that EPO is functionally active in the ovine fetal membranes and that the membranes could be one of the sources of EPO in the amniotic fluid.19 The relative contributions of potential sources of EPO and the transport mechanisms of fetal EPO into the amniotic fluid in human pregnancy is currently unknown. To address this potentially clinically important issue, there is an urgent need for this to be studied both in animal models and human pregnancies.

Chronic fetal hypoxia and EPO

As in adults, tissue hypoxia in the fetus is the major stimulus of EPO production.8 In adults, plasma EPO levels start to increase 90 min after the beginning of acute hypoxia, with the magnitude of the increase correlating directly with the duration and severity of hypoxia.20 In the fetal sheep, plasma EPO levels begin to increase 3–4 h after a massive acute hemorrhage or after induction of moderate to severe fetal hypoxia.21, 22 In human pregnancy both umbilical cord plasma and amniotic fluid EPO levels correlate inversely with umbilical artery (UA), pH, base excess and pO2, and directly with pCO2 and lactate in cases of fetal chronic hypoxia.6, 14, 15, 17, 23–25 In the fetal sheep, plasma EPO levels start to increase exponentially when the arterial oxygen content falls below 60% of normal.26 A similar exponential increase in amniotic fluid EPO levels has been observed in human type 1 diabetic pregnancies when UA pO2 levels decrease below 2.0 kPa (15.0 mmHg).14

Hypoxia increases both reactive oxygen species (ROS)27, 28 and reactive nitrogen species (RNS).27 The degree of fetal oxidative stress can be quantitated by measuring the concentration of specific oxidative and nitrosative stress biomarkers in amniotic fluid.29 In support of this we have reported in diabetic pregnancies that amniotic fluid EPO levels correlate highly significantly with two amniotic fluid oxidative stress biomarkers (meta-L-tyrosine/Phen and 8-pyrodoC/2dG ratios) and one nitrosative stress biomarker (3-nitro-L-tyrosine/Phen ratio) (r = 0.59, r = 0.93, and r = 0.90, all p < 0.001).27 While this association further emphasizes the importance of fetal EPO level as a marker of intrauterine hypoxia, the nature of and the possible mechanisms responsible for this association are unknown. Once discovered, new therapeutic approaches might become apparent.

Increased fetal umbilical cord blood or amniotic fluid EPO levels have been reported in a broad spectrum of pregnancies in which fetal hypoxia occurs. These include prolonged pregnancies31 and pregnancies complicated by meconium-stained amniotic fluid,32 growth-restricted fetuses,15, 23, 24 abnormal fetal heart rate recordings,25, 26 type 1 diabetes,14 hypertension,15 and severe fetal anemia.17 While clinical evidence of increased hypoxia in fetuses or asphyxia in newborn infants are common among all these abnormal antepartum situations, the pathogenic mechanisms leading to fetal hypoxia differ among these conditions.

Placental EPO production

In the ovine fetus, a switch of EPO synthesis from the kidneys to the placenta occurs during hypoxia.18 In the study by Davis et al.,38 placental production of EPO was not observed during normal fetal oxygenation. However, after inducing fetal hypoxia, umbilical vein (UV) EPO concentrations increased to levels 13% higher than UA concentrations, thereby suggesting increased placental EPO production. The investigators calculated that the placenta produced 1.1 million mU of EPO per hour during hypoxia. This value is 15 times greater than simultaneously measured EPO production by the fetal kidneys.38 Similarly, when we measured UV and UA EPO plasma concentrations separately at birth in type 1 diabetic pregnancies delivered during elective cesarean section before labor, UV EPO levels were significantly higher than UA levels in hypoxic fetuses with UA pO2 below 2 kPa (15 mmHg) at delivery.29 In addition, our observation that the UV/UA plasma EPO ratio correlated inversely with UA pO2 further indicates that placental EPO production increases during fetal hypoxia. We, therefore, speculate that the observed increased fetal plasma EPO concentrations in human pregnancy is at least partially a function of the increased placental EPO synthesis during fetal hypoxia in order to protect the fetal brain and other vital organs (Fig. 1).

Although EPO protein, mRNA and receptors are all present in both the human and ovine placenta,40, 41 their functional importance for the fetus is not well understood. Clearly, the transport mechanisms of placental EPO hormone into the fetal circulation needs to be delineated during normal and hypoxic conditions in human pregnancies.

In addition to these uncertainties of placental EPO production and transport, very little is known about how factors such as choorioamnionitis or drugs might interfere with, or otherwise modulate fetal EPO production and transport. If our hypothesis that fetal EPO synthesis is increased during fetal hypoxia to protect its brain and other vital organs is correct, it will emphasize the clinical importance and utility of antenatal EPO measurement in amniotic fluid and fetal plasma at birth. This is especially important in pregnancies at an increased risk of fetal hypoxic sequelae. Finally, the use of amniotic fluid EPO levels as an antenatal hypoxia marker and predictor of poor neurodevelopmental outcome needs to be addressed in adequately powered single and multi-center randomized clinical trials. It is imperative that such randomized clinical trials include follow-up studies of subsequent cognitive functions.

Role of EPO in tissue protection

In addition to its role in hematopoietic regulation, EPO also has tissue-protective properties.41–43 This is the result of EPO receptor (EPO-R) isoforms, which differ structurally and functionally from the hematopoietic EPO-R isoform. Different EPO-Rs exert both short- and long-term tissue-protective effects.44, 45 Acute, short-term EPO effects are mediated by its anti-inflammatory, anti-apoptotic, and angiogenic properties.43–47 Long-term EPO effects are those promoting more gradual processes, including erythropoiesis, angiogenesis, and neurogenesis.42 In vivo and in vitro studies indicate that high EPO concentrations and short receptor occupancy are required to activate the tissue-protective isoform of EPO-R with a relatively low EPO affinity.41 In contrast, much lower but sustained concentrations of EPO are needed for the regulation of erythropoiesis as the high-affinity EPO-R isoform is expressed by proerythrocytes during erythrocyte maturation.11, 13, 41

**EPO and the fetal brain.** During acute and chronic hypoxia, the fetus redistributes cardiac output to maintain adequate oxygen supply to the brain. This brain-sparing redistribution of cardiac output is a well known fetal adaptive mechanism to counteract deleterious effects of chronic hypoxia.44 In addition, local EPO production has been shown to take place in the fetal brain.45 This is based on EPO and EPO-R gene expression in astrocytes, glial cells, neurons, and brain endothelial cells.46 In asphyxiated newborn infants in the first two days of life, cerebrospinal fluid (CSF) EPO concentrations correlate highly significantly with concurrent plasma EPO concentrations (r = 0.99, p < 0.0001).47 Hence, local endogenous EPO production in CNS tissue is another adaptive mechanism to attenuate the harmful effects of hypoxia on the brain.48
Numerous preclinical, and more recently, clinical studies in preterm newborn infants have shown that exogenously administered recombinant human EPO (rhEPO) has neuroprotective effects in the brain (for review see ref.42). As proof that EPO can cross the blood-brain barrier, marked increases in CSF EPO levels are observed in fetal sheep within 2–4 h after a high dose of parenteral rhEPO to levels shown to offer tissue protection from hypoxia.49, 50 What remains uncertain is whether the high EPO levels in the CSF are caused by high plasma EPO levels crossing the blood-brain barrier during hypoxia or the result of local EPO production by brain tissue (Fig. 1). This missing information has important therapeutic implications. It is noteworthy that EPO concentrations of over 10,000 mU/ml have been measured in cord blood plasma at birth of asphyxiated fetuses.14, 15 Hence, we infer that EPO can cross the fetal blood-brain barrier in human pregnancies. There is growing evidence that preterm infants weighing <1000 g at birth experience neuroprotective benefit from rhEPO treatment given to stimulate erythropoiesis.51 Newborn infants with severe intraventricular hemorrhage receiving rhEPO had better neurodevelopmental outcome at the age of 10 to 13 years than those not receiving rhEPO during the neonatal period.51 Although therapeutic body cooling is presently the method of choice of term newborn infants suffering from hypoxic-ischemic encephalopathy (HIE), almost half of HIE survivors have severe neurologic sequelae. High dose rhEPO parenteral treatment added to cooling treatment of newborn infants with HIE resulted in smaller brain injury volume than cooling treatment alone as detected by MRI.52 As expected, the neurodevelopmental outcome was poorer at 12 months of age among the newborn infants receiving cooling treatment alone compared to those receiving both EPO and cooling treatment.52

Amniotic fluid and the neonatal intestine. Amniotic fluid contains a large number of cytokines, including EPO, and antimicrobial peptides known to influence the development of fetal gastrointestinal tract.53, 54 It is noteworthy that NEC does not exist in the fetus, which has led to the speculation that amniotic fluid has protective effects against NEC.54 Although the possible protective functions of amniotic fluid against NEC has recently been reviewed,55 a plausible explanation of how amniotic fluid exerts its protective effects against NEC in the newborn infant has not been given.55 It is well known that perinatal asphyxia is associated with neonatal gut injury, impaired intestinal motility, and NEC.56–58 Notably, EPO receptors are present both in human and rat enterocytes.59 Parenteral rhEPO given to newborn infants weighing <1250 g at birth has been associated with a decrease in the incidence of NEC.60 Moreover, in a neonatal rat model of NEC, exogenous EPO has been shown to protect intestinal cells both in vitro and in vivo61 and to stimulate vasculogenesis of microvascular endothelial intestine cells.62 In a recent randomized controlled study in preterm newborns both recombinant human granulocyte colony-stimulating factor (rhG-CSF) and rhEPO, administered enterally separately or in combination during the first days of life, decreased the risk of NEC and improved feeding outcomes.63

An important unanswered question with potential therapeutic implications for NEC is why amniotic fluid EPO concentration increases exponentially during fetal hypoxia.14, 15, 17 We hypothesize that high amniotic fluid EPO concentrations associated with fetal hypoxia exert beneficial effects on the fetal and neonatal intestine as a result of fetal swallowing of amniotic fluid with high EPO concentration (Fig. 1). It is well known that the near-term fetus swallows up to 700 ml of amniotic fluid daily.64, 65 In this regard, it is noteworthy that EPO in milk resists degradation in the intestine of the newborn infant.66, 67 Although EPO concentrations greater than 1500 mU/ml have been measured in the amniotic fluid during fetal hypoxia,14, 15 the potential beneficial effects of these markedly increased levels of amniotic fluid EPO in reducing neonatal intestine hypoxic tissue injury has yet to be determined. If these beneficial effects are shown, therapeutic EPO given enterally or parenterally would be the next important step to study.

The current widely accepted practice of human milk feeding as an important approach to NEC prevention in preterm newborn infants45 lends further support to our hypothesis that increased amniotic fluid EPO levels exert beneficial effects on the fetal and neonatal intestine. The beneficial effects of human milk on the intestine of preterm newborn infants has been shown at least in part to be due to high levels of EPO and other growth factors in the breast milk.57 EPO levels in human milk are similar to maternal plasma EPO levels in the early postpartum period. EPO levels in breast milk increase above maternal plasma EPO levels during ongoing nursing, thus suggesting active secretion of EPO by the mammary gland58 (Fig. 1).

Presently, there is controversy whether enteral EPO is absorbed intact into the circulation of the newborn offspring.69, 70 In a rat model, parenterally increased plasma EPO in dams did not increase plasma EPO levels or hematocrit in suckling rats compared with controls.70 However, enterally administered 125I-rhEPO did show enteral absorption in suckling rats with 5% of the total EPO dose administered being found in the plasma and another 8–10% localized in the bone marrow.59 Radiolabeled rhEPO was also found localized in liver and other solid tissues. In suckling rats, a high dose of EPO (1700 U kg−1 × day−1) fed artificially together with iron sulfate was shown to increase hemoglobin levels.71 In another study, enteral administration of EPO to preterm infants was shown to stimulate erythropoiesis.72

It can be concluded from these studies that enteral absorption of EPO into the circulation seems possible. Nonetheless, it is clear that more studies are needed to delineate the circumstances that determine enteral absorption of EPO in newborns. Whether enteral absorption of EPO into the fetal circulation also occurs with swallowed amniotic fluid EPO in human pregnancies is unknown.

In conclusion, in addition to the role of EPO as a regulator of erythropoiesis, EPO also exerts both short- and long-term tissue-protective effects. This dual role of EPO is based on different EPO receptor isoforms. Notably, EPO’s tissue-protective effect requires markedly higher EPO concentrations than its hematopoietic effects. In human pregnancy, we and others have measured extremely high levels of EPO in fetal plasma and in the amniotic fluid. The functional significance of this is not well understood. Here, we hypothesize that the fetus increases its EPO production in order to protect its brain and other vital organs. We further hypothesize, based on fetal swallowing of amniotic fluid, that the fetus increases amniotic fluid EPO levels during fetal hypoxia to protect the intestine during the neonatal period. In this Mechanistic Integrated Review, we suggest a new way of looking at the effects of EPO on fetal erythropoiesis, as well as EPO’s central nervous and gut tissue-protective properties. Our hypotheses are based on a review the literature of both experimental and clinical studies. If our hypotheses are correct, the importance of fetal EPO as an antenatal hypoxia biomarker and therapeutic agent will become apparent and provide an urgently needed impetus for confirming our hypotheses and exploring fetal EPO’s diagnostic and therapeutic potential.
